Abstract. *Focused proof systems* provide means for reducing and structuring the non-determinism involved in searching for sequent calculus proofs. We present a focused proof system for a first-order logic with inductive and co-inductive definitions in which the introduction rules are partitioned into an *asynchronous* phase and a *synchronous* phase. These focused proofs allows us to naturally see proof search as being organized around interleaving intervals of computation and more general deduction. For example, entire Prolog-like computations can be captured using a single synchronous phase and many model-checking queries can be captured using an asynchronous phase followed by a synchronous phase. Leveraging these ideas, we have developed an interactive proof assistant, called Tac, for this logic. We describe its high-level design and illustrate how it is capable of automatically proving many theorems using induction and coinduction. Since the automatic proof procedure is structured using focused proofs, its behavior is often rather easy to anticipate and modify. We illustrate the strength of Tac with several examples of proof developments, some achieved entirely automatically and others achieved with user guidance.

1 Introduction

The sequent calculus of Gentzen is a well-studied proof framework used to describe provability for a number of logics. This framework also seems to be a natural setting for organizing the search for proofs in a theorem prover. For example, a sequent of the form $\Sigma; \Gamma \vdash B$ denotes the obligation of showing that the formula B follows from the assumptions in the (multi)set Γ for every instantiation of the variables in Σ . An attempt to prove a formula, say B_0 , then gives rise to attempts to apply inference rules repeatedly to the root sequent $;\cdot \vdash B_0$ leaving, at some point, open premises $\Sigma_1; \Gamma_1 \vdash B_1, \dots, \Sigma_n; \Gamma_n \vdash B_n$. This set of sequents represent one way to decompose the original proof obligation into $n \geq 0$ subgoals. The frontier of the open proof tree can represent the abstract state of an idealized theorem prover.

The sequent calculus is, unfortunately, far too non-deterministic to directly organize a theorem prover. For example, consider the case when there are even just two hypotheses on which to work. The sequent calculus does not specify on which to work first, and so one might first work on one, then the other, alternating back and forth. This creates an explosive number of alternatives

to explore, many of which are often redundant. Similarly, the structural rules of weakening and contraction can be applied, in principle, to every formula anytime.

Anyone who has attempted to build a theorem prover based on the sequent calculus (or related systems such as tableaux) has undoubtedly observed that there are different ways to give some structure to many of these choices. For example, some inference rules are invertible and, as a result, choices in the order of their application do not affect provability. Additionally, sometimes when a formula is introduced it no longer needs to be maintained: thus the contraction rule need not be considered for that formula. Finally, sometimes selecting one formula for introduction can be seen as causing a cascade of other introduction rules. In recent years, a series of *proof theory* papers have appeared that present various *focused proof systems* for classical and intuitionistic logic. These new proof systems formalize exactly these kinds of observations and turn them into elegant and deep normal form theorems.

Focused proof systems require classifying connectives into two *polarities*, called synchronous and asynchronous: connectives of the same polarity are then aggregated into a single *synthetic* connective. From a proof-search point of view, asynchronous connectives can be introduced early and in any order, since these connectives generally have invertible inference rules. In contrast, once a synchronous formula has been chosen for introduction, then all synchronous subformulas must also be selected immediately for introduction: the synchronous phase ends when the proof is finished or only asynchronous subformulas are reached. Focused proof systems are then used to introduce such synthetic connectives, building their introduction rule from collections of individual, small, introduction rules. The identification of synthetic connectives allows us to view proof search in sequent calculus as revolving around *big step* inference rules and not the usual *small step* introduction rules of Gentzen. Furthermore, since the proof theory behind focused proof systems for classical and intuitionistic logic contains some ambiguity (for example, conjunctions and atoms can be considered as being part of an asynchronous or a synchronous phase), the theorem prover designer has some flexibility in what she wants to have as a synthetic connective. Thus, the big step inference rules can be engineered to some extent. The formal results about focused proof systems provide a solid foundation for these engineered, big-step inference rules: they remain sound and complete with respect to the original small-step proof system.

From the perspective of designing a theorem prover, the above concepts are invaluable. As we shall see, focusing allows mixing computation and deduction in natural and transparent ways. For example, it is entirely possible to describe, say, the concatenation of two lists (in the relational style of Prolog) and then embed the entire computation of such a relationship within one synthetic connective. This is in striking contrast with the treatment in most resolution-style theorem provers where such a computation is emulated by a possibly large number of small-step resolution rules. Going one step further, a model-checking problem (*e.g.*, all members of one finite set are members of another set) can be naturally modeled as just two synthetic connectives: the first asynchronous and the second

synchronous. Thus, the high-level viewpoint of proof brought by the notion of *synthetic connective* can make for more effective proof-search.

In this paper, we present the design and applications of an automatic theorem prover, called Tac. Section 2 introduces μLJ , the logic underlying Tac: it is an intuitionistic logic containing least and greatest fixed points. Section 3 provides a focused proof system for μLJ . In Section 4, we describe the high-level design of Tac, in particular its automatic proof-search strategy involving the use of (co)induction. This design has been governed by the following three principles. First, while Tac is an interactive prover based on tacticals, it is hoped that a single, automatic tactic can be used to fill in the gaps between a theorem and a list of (human supplied) lemmas. Second, the automatic tactic is organized around the search for focused proofs via the use of synthetic connectives. Third, the only influence we allow ourselves on the automatic tactic's behavior (apart from the choice of lemmas) involves those aspects of focused proof systems that proof theory has not fixed as canonical. Section 5 summarizes the behavior of Tac and compares it to some other theorem proving systems.

2 The logic μLJ

The logic μLJ is the extension of first-order intuitionistic logic with inductive and coinductive definitions given using least and greatest fixed points. The proof system for μLJ contains familiar rules for inductive and coinductive inference based on the selection of invariants. It notably provides the intuitionistic version of Peano's arithmetic. While the proof-theory of μLJ is related to that given for μMALL in [4, 2], the particular focused proof system presented below has not yet been published.

We consider the following simply typed language of formulas:

$$P ::= P \wedge P \mid P \vee P \mid P \supset P \mid \perp \mid \top \\ \mid \exists_{\gamma} x. P \mid \forall_{\gamma} x. P \mid s \stackrel{\gamma}{=} t \mid \mu_{\gamma_1 \dots \gamma_n} (\lambda p \lambda x. P) t \mid \nu_{\gamma_1 \dots \gamma_n} (\lambda p \lambda x. P) t.$$

The syntactic variable γ represents a term type, *e.g.*, natural numbers and lists. The quantifiers have type $(\gamma \rightarrow o) \rightarrow o$ and the equality has type $\gamma \rightarrow \gamma \rightarrow o$. The least fixed point connective μ and the greatest fixed point connective ν have type $(\tau \rightarrow \tau) \rightarrow \tau$ where τ is $\gamma_1 \rightarrow \dots \rightarrow \gamma_n \rightarrow o$ for some arity $n \geq 0$. We shall almost always elide the references to γ , assuming that they can be determined from the context when it is important to know their value. Note that we do not consider atoms, *i.e.*, predicate constants: although μLJ accomodates them without any problem, atoms are often unnecessary since fixed points play their role in practice, and thus we leave them out for simplicity.

Formulas with top-level connective μ or ν are called fixed point expressions. Fixed points can be arbitrarily nested and interleaved — that is, we can have mutually recursive definitions. The first argument of a fixed point connective is a predicate operator expression, called its *body*, and shall be denoted by B . In order for the logic to enjoy consistency and other useful properties, all fixed

point bodies are required to be *monotonic*, *i.e.*, there should be no negative occurrence of the bound predicate variable p in $\lambda p \lambda x. Bp x$.

Example 1. Assuming a term type n and two constants $0 : n$ and $s : n \rightarrow n$, the natural number predicate nat of type $n \rightarrow o$ can be defined as the inductive expression μB_{nat} , where B_{nat} is defined as $\lambda N \lambda x. x = 0 \vee \exists y. x = s y \wedge N y$.

The inference rules of μLJ deal with usual first-order intuitionistic sequents, of the form $\Sigma; \Gamma \vdash P$ where Σ is a set of universal (eigen)variables x_1, \dots, x_n and Γ is a set of formulas P_1, \dots, P_m . The logical reading of such a sequent is $\forall x_1 \dots \forall x_n. (P_1 \wedge \dots \wedge P_m \supset P)$.

The inference rules of μLJ are the usual ones for the propositional connectives and first-order quantifiers. The left and right-introduction rules for equality,

$$\frac{\{(\Sigma; \Gamma \vdash Q)\theta : \theta \in csu(t \doteq t')\}}{\Sigma; \Gamma, t = t' \vdash Q} \quad \text{and} \quad \frac{}{\Sigma; \Gamma \vdash t = t}$$

date back to [6, 12]. In the left equality rule, csu stands for *complete set of unifiers* [7]. This set can be restricted to have at most one element when terms are first-order but might be infinite if terms are interpreted modulo some algebraic theory or if they are simply typed λ -terms. The application of a substitution to the signature of a sequent consists in removing instantiated variables and adding newly introduced ones; the application to the rest of the sequent simply propagates it to the terms of every formula. Note that this treatment of equality is stronger than Leibniz equality, as it notably expresses the injectivity of term constructors. Our treatment of equality provides our proof system with an approach to *negation-as-failure*: if the equality $t = t'$ is a *failure* (that is, $csu(t, t')$ is empty) then the equality left rule yields a *successful* proof (that is, there are no premises to the rule).

The least fixed point μB is characterized as the least of the prefixed points.

$$\frac{\Sigma; \Gamma, St \vdash P \quad x; BSx \vdash Sx}{\Sigma; \Gamma, \mu Bt \vdash P} \quad \frac{\Sigma; \Gamma \vdash B(\mu B)t}{\Sigma; \Gamma \vdash \mu Bt}$$

The right *unfolding* rule expresses $B(\mu B)t \supset \mu Bt$, and the left *induction* rule expresses that μB entails any prefixed point S , also called an *invariant*. Notice that the universal variables x in the induction rule are new.

From the induction rule one can always derive a left unfolding rule for μ , using the invariant $B(\mu B)$:

$$\frac{\Sigma; \Gamma, B(\mu B)t \vdash P}{\Sigma; \Gamma, \mu Bt \vdash P}$$

Thus, the least prefixed point is a fixed point, *i.e.*, μBx and $B(\mu B)x$ are provably equivalent. The introduction rules for greatest fixed points are the dual rules

$$\frac{\Sigma; \Gamma, B(\nu B)t \vdash P}{\Sigma; \Gamma, \nu Bt \vdash P} \quad \text{and} \quad \frac{\Sigma; \Gamma \vdash St \quad x; Sx \vdash BSx}{\Sigma; \Gamma \vdash \nu Bt}.$$

$$\begin{aligned}
eq &\stackrel{def}{=} \mu(\lambda E \lambda x \lambda y. (x = 0 \wedge x = 0) \vee (\exists x' \exists y'. x = s \ x' \wedge y = s \ y' \wedge E \ x' \ y')) \\
leq &\stackrel{def}{=} \mu(\lambda L \lambda x \lambda y. x = y \vee (\exists y'. y = s \ y' \wedge L \ x \ y')) \\
half &\stackrel{def}{=} \mu(\lambda H \lambda x \lambda h. ((x = 0 \vee x = s \ 0) \wedge h = 0) \\
&\quad \vee (\exists x' \exists h'. x = s^2 \ x' \wedge h = s \ h' \wedge H \ x' \ h')) \\
append &\stackrel{def}{=} \mu(\lambda A \lambda x \lambda y \lambda z. (x = nil \wedge y = y) \\
&\quad \vee (\exists e \exists x' \exists z'. x = e :: x' \wedge z = e :: z' \wedge A \ x' \ y \ z')) \\
reverse &\stackrel{def}{=} \mu(\lambda R \lambda l \lambda r. (l = nil \wedge r = nil) \\
&\quad \vee (\exists h \exists l' \exists r'. l = h :: l' \wedge R \ l' \ r' \wedge append \ r' \ (h :: nil) \ r)) \\
sublist &\stackrel{def}{=} \mu(\lambda S \lambda l \lambda l'. \exists a \exists b \exists r. append \ a \ l \ r \wedge append \ r \ b \ l') \\
sorted &\stackrel{def}{=} \mu(\lambda S \lambda l. l = nil \vee (\exists x. l = x :: nil) \\
&\quad \vee (\exists x \exists y \exists l'. l = x :: y :: l' \wedge leq \ x \ y \wedge S \ (y :: l))) \\
sim &\stackrel{def}{=} \nu(\lambda S \lambda p \lambda q. \forall l \forall p'. step \ p \ a \ p' \supset \exists q'. step \ q \ a \ q' \wedge S \ p' \ q')
\end{aligned}$$

Fig. 1. Examples of fixed point expressions

Finally, the initial rule can be restricted to fixed point expressions. For brevity, we shall omit the signature Σ from the sequents in the next sections; its treatment should be clear from these paragraphs.

Example 2. In the particular case of *nat*, the induction rule with invariant S yields the usual induction principle:

$$\frac{\Gamma, S \ t \vdash P \quad \frac{\vdash S(0) \quad S(y) \vdash S(s \ y)}{(B_{nat} S)x \vdash Sx} \vee L, \exists L, \wedge L, =L}{\Gamma, nat \ t \vdash P}$$

The logic μLJ results from a line of work on definitions [6, 12] and induction and coinduction [9, 11]. The presentation using μ and ν makes for a more direct proof theoretical study, and notably naturally brings the possibility to treat mutual (co)inductive definitions in an expressive way. Figure 1 contains several example fixed point definitions. These examples use *nil* as the empty list constructor and $::$ as the non-empty list constructor.

3 Focused proofs for μLJ

The proof system for μLJ described in the previous section is *unfocused* since there is no particular structure imposed on how one occurrence of an inference rule relates to another. In contrast, a focused proof system classifies inference rules into synchronous and asynchronous ones and then groups those of similar classification into one “synthetic introduction rule”. The first focused proof

system for a full logic was given by Andreoli for linear logic [1]. Eventually, focused proof systems have been developed for other logics where it was revealed that proof theory concerns did not fix all polarization choices (in particular, for atoms [1], conjunctions [8], and fixed points [2]). As a result, these non-fixed items could be placed into either the asynchronous or the synchronous phases: such choices do not affect provability but can have a striking effect on the size and shape of proofs. In linear logic, asynchronous connectives were exactly those with invertible right-introduction rules. That simple connection may not hold for richer logics, such as μLJ : indeed, fixed points can always be treated in an invertible way (provability is never lost by unfolding) but completeness cannot be obtained with a strategy that eagerly unfolds all fixed points. For example, proving $\text{nat } x \vdash \text{nat } x$ cannot succeed by repeatedly unfolding the hypothesis; at some point, one has to stop unfolding and, instead, use the initial rule.

Definition 1 (Polarities for μLJ). *The connectives $\wedge, \vee, \exists, =$, and μ are synchronous while the connectives \forall, \supset and ν are asynchronous. A synchronous (resp. asynchronous) formula is one whose top-level connective is synchronous (resp. asynchronous). If every connective of a formula is synchronous (resp. asynchronous), it is called fully synchronous (resp. asynchronous). Finally, a fixed point formula can be annotated as frozen, which is denoted by $(\mu Bt)^*$ and $(\nu Bt)^*$, in which case it is neither synchronous nor asynchronous.*

Figures 2, 3 and 4 present μLJF , a focused proof system for μLJ . There are two kinds of sequents: the *unfocused sequent* is written $\Gamma \vdash P$ (as before) and the *focused sequent* is written with a bracketed formula (the focus) as either $\Gamma \vdash [P]$ or $\Gamma, [P] \vdash Q$. In each of these sequents, Γ is a multiset of formulas. There is an unsurprising symmetry between left and right hand-sides of sequents: a synchronous connective is treated as asynchronous on the left and *vice-versa*. The *asynchronous phase* contains sequents of the form $\Gamma \vdash P$ and introduces asynchronous connectives on the right and synchronous ones on the left. The *synchronous phase* contains sequents containing one distinguished (bracketed) formula that is *under focus*. When the focus is on the right ($\Gamma \vdash [P]$) only the synchronous connectives of P can be introduced. When the focus is on the left ($\Gamma, [P] \vdash Q$) only asynchronous connectives of P can be introduced. The articulation between the two phases is allowed only when no other rule applies: the asynchronous phase ends when no synchronous formula remains on the left, and the conclusion is synchronous; the synchronous phase ends when the focus is on the left on a synchronous formula, or on the right on an asynchronous one. Finally, the structural rule of contraction is used (implicitly) only in the rule establishing a left focus formula — and thus, only for asynchronous formulas.

Each fixed point has two rules per phase: one of these rules treats the fixed point as a structured formula; the other treats it as an atom. The synchronous rules are unfolding and the initial rule and the asynchronous rules are (co)induction and *freezing*. A strong constraint of the asynchronous phase is that it requires that any least fixed point hypothesis (and greatest fixed point conclusion) is either immediately used for (co)induction (which includes unfolding)

$$\begin{array}{c}
\frac{\Gamma, P, P' \vdash Q}{\Gamma, P \wedge P' \vdash Q} \quad \frac{\Gamma, P \vdash Q \quad \Gamma, P' \vdash Q}{\Gamma, P \vee P' \vdash Q} \quad \frac{\Gamma, P \vdash Q}{\Gamma \vdash P \supset Q} \quad \frac{}{\Gamma, \perp \vdash P} \quad \frac{\Gamma \vdash P}{\Gamma, \top \vdash P} \\
\\
\frac{\Gamma \vdash Px}{\Gamma \vdash \forall x. Px} \quad \frac{\Gamma, Px \vdash Q}{\Gamma, \exists x. Px \vdash Q} \quad \frac{\{(\Gamma \vdash P)\theta : \theta \in csu(t \doteq t')\}}{\Gamma, t = t' \vdash P} \\
\\
\frac{\Gamma, St \vdash P \quad BSx \vdash Sx}{\Gamma, \mu Bt \vdash P} \quad \frac{\Gamma, (\mu Bt)^* \vdash P}{\Gamma, \mu Bt \vdash P} \quad \frac{\Gamma \vdash St \quad Sx \vdash BSx}{\Gamma \vdash \nu Bt} \quad \frac{\Gamma \vdash (\nu Bt)^*}{\Gamma \vdash \nu Bt}
\end{array}$$

Fig. 2. μ LJF: asynchronous rules

$$\begin{array}{c}
\frac{\Gamma \vdash [P] \quad \Gamma \vdash [P']}{\Gamma \vdash [P \wedge P']} \quad \frac{\Gamma \vdash [P_i]}{\Gamma \vdash [P_0 \vee P_1]} \quad \frac{\Gamma, [P'] \vdash Q \quad \Gamma \vdash [P]}{\Gamma, [P \supset P'] \vdash Q} \quad \frac{}{\Gamma \vdash [\top]} \\
\\
\frac{\Gamma, [Pt] \vdash Q}{\Gamma, [\forall x. Px] \vdash Q} \quad \frac{\Gamma \vdash [Pt]}{\Gamma \vdash [\exists x. Px]} \quad \frac{}{\Gamma \vdash [t = t]} \\
\\
\frac{\Gamma, [B(\nu B)t] \vdash P}{\Gamma, [\nu Bt] \vdash P} \quad \frac{}{\Gamma, [\nu Bt] \vdash (\nu Bt)^*} \quad \frac{\Gamma \vdash [B(\mu B)t]}{\Gamma \vdash [\mu Bt]} \quad \frac{}{\Gamma, (\mu Bt)^* \vdash [\mu Bt]}
\end{array}$$

Fig. 3. μ LJF: synchronous rules

$$\frac{\Gamma, Q, [Q] \vdash P}{\Gamma, Q \vdash P} \quad \frac{\Gamma \vdash [P]}{\Gamma \vdash P} \quad \frac{\Gamma, P \vdash Q}{\Gamma, [P] \vdash Q} \quad \frac{\Gamma \vdash Q}{\Gamma \vdash [Q]}$$

Fig. 4. μ LJF: structural rules (P synchronous, Q asynchronous)

or frozen, in which case it can never again be unfolded or used for induction: it can only be used in an initial rule later in the proof. Also note that when one focuses on a fully synchronous least fixed point, such as *nat* and all predicates of Figure 1 except *sim*, focus can never be released. Hence, the proof has to be completed in that phase, eventually reaching units, equality, or the initial rule if an appropriate frozen side-formula is available.

The standard, unfocused proof system for μ LJ can be recovered from μ LJF by removing all focusing annotations.

Theorem 1 (Completeness [2]). *The sequent $\Gamma \vdash P$ is provable in μ LJ if and only if it is provable in μ LJF.*

Although not visible in the statement of completeness, the asynchronous rules can be applied in any order — permuting them actually leaves the proof essentially unchanged.

As usual, the completeness of the focused proof system justifies a reading of logic based on synthetic connectives and synthetic introduction rules. A synthetic introduction rule for a synthetic synchronous connective is a big-step rule that has a focused sequent as its conclusion and which extends upwards until there are only unfocused sequents present. Dually, a synthetic introduction rule for

a synthetic asynchronous connective is a big-step rule that has an unfocused sequent as its conclusion and which extends upwards until no asynchronous rule can be applied. Note that this is especially powerful with fixed points, since we can now have synthetic introduction rules built from unbounded numbers of micro-rules. An interesting particular case of this is that of fully synchronous formulas, such as *nat* and more generally any Prolog-style computation, which constitute a synthetic unit, with an infinity of synthetic introduction rules.

Example 3. Consider the synthetic introduction rule that ends with the right-focused sequent $\Gamma \vdash [(leq\ m\ n \wedge B_1) \vee (leq\ n\ m \wedge B_2)]$, where m and n are natural numbers (terms over s and 0) and *leq* is the purely synchronous fixed point in Figure 1 denoting the less-than-or-equal-to relation. If both B_1 and B_2 are asynchronous formulas, then there are exactly two possible synthetic rules: one with premise $\Gamma \vdash B_1$ when $m \leq n$ and one with premise $\Gamma \vdash B_2$ when $n \leq m$ (thus, if $m = n$, both premises are possible). In this sense, a synthetic synchronous connective can contain an entire Prolog-style computation.

The value of a focused proof system for μLJ is not that it makes theorem proving technically easier but rather that organizing the elements of search around synthetic connectives should be easier to understand for a human interacting with the theorem prover. We now turn to the main contribution of this paper: the design of an automatic tactic that is organized around synthetic connectives.

4 Tac

There are several ways to exploit focusing for proof-search. For instance, the inverse method — performing top-down proof-search — yields impressive results when combined with focusing [5, 10]. Proof search that must generate (co)invariants is hard to do in such a top-down style, particularly when contexts are used to generate the (co)invariants. Thus, we use bottom-up proof search. As we outline next, that choice is also compatible with the use of tactics and tacticals in a proof assistant.

Tac is built around a small kernel implementing elementary operations and (small-step) inference rules. The reversing of inference rules gives rise to primitive tactics. Tactics are then organized into larger tactics using tacticals such as **then**, **repeat**, etc. The successful application of a series of tactics to prove a theorem triggers the production of a proof, which can be inspected. There is no support for any particular datatypes.

Focusing is built into the foundations of Tac: formulas are annotated with polarity information and that information is used to guide the application of logical rules. Such annotations are useful not only for the automation of inductive proof search but also for human interaction. For example, the tactic **async** simplifies a goal by repeatedly applying asynchronous rules, the common tactic **apply** actually consists of focusing on a lemma and performing a synchronous phase, and the tactic **freeze** is used to prevent induction and thereby guide

automated theorem proving. Finally, we also use focusing to display proofs more concisely by showing synthetic inference rules instead of the “micro” rules.

In the following, we concentrate on the essential ingredients of our automated tactic, called **prove**. We first describe how to identify computation, then how to deal with the salient reasoning step of finding (co)invariants, and finally describe the overall structure of the tactic.

4.1 Progress

We generally think of proof search as being a process composed primarily of deduction, but of course large portions of a particular proof may be given over to computation. Any implementation of proof search should recognize and exploit this distinction, not only for efficiency (computations should not involve (co)inductions or certain other deductive techniques) but also for robustness and predictability. Focusing allows us to circumscribe computations to single phases, even if that computation is non-deterministic. A useful fragment to identify is that of deterministic computation. For example, given the goal $\forall x. \text{mult } 10 \ 10 \ x \supset P \ x$ or the goal $\exists x. \text{mult } 10 \ 10 \ x \wedge P \ x$, the prover should compute the value of x immediately in a single step. The notion of *progressing unfolding* presented below allows us to do so and, in fact, to treat these examples in exactly the same way.

Definition 2 (Patterns). A pattern \mathcal{C} of type $\gamma_1, \dots, \gamma_n \rightarrow \gamma'_1, \dots, \gamma'_m$ is a vector of m elementary patterns p_i , which are themselves closed terms of type $\gamma_1, \dots, \gamma_n \rightarrow \gamma'_i$. The input arity of the pattern is n , and m is its output arity. Both can be zero. When \mathbf{t} is a vector of terms $\langle t_1 : \gamma_1, \dots, t_n : \gamma_n \rangle$, the expression $\mathcal{C}\mathbf{t}$ denotes the vector $\langle p_1\mathbf{t}, \dots, p_m\mathbf{t} \rangle$. For two vectors of terms of equal length n , the expression $\mathbf{t} = \mathbf{t}'$ denotes the formula $t_1 = t'_1 \wedge \dots \wedge t_n = t'_n$.

Definition 3 (Matcher). Let \mathcal{C} be a vector $\langle \mathcal{C}_1, \dots, \mathcal{C}_n \rangle$ of patterns, all of the same output arity m . The matcher $M_{\mathcal{C}}$ is defined as the term:

$$M_{\mathcal{C}} \stackrel{\text{def}}{=} \lambda\phi_1 \dots \lambda\phi_n \lambda x_1 \dots \lambda x_m. (\exists \mathbf{y}_1. \mathbf{x} = \mathcal{C}_1 \mathbf{y} \wedge \phi_1 \mathbf{y}) \vee \dots \vee (\exists \mathbf{y}_n. \mathbf{x} = \mathcal{C}_n \mathbf{y} \wedge \phi_n \mathbf{y})$$

Example 4. We can define *nat* from the matcher on the patterns $\mathcal{C}_1 := \langle 0 \rangle$ and $\mathcal{C}_2 := \langle \lambda p. s \ p \rangle$ by $\text{nat} := \mu(\lambda N \lambda x. M_{\mathcal{C}} \top N x)$. The fixed point *half* is built on the patterns $\langle 0, 0 \rangle$, $\langle s \ 0, 0 \rangle$, and $\langle \lambda p. s^2 p, \lambda p. s \ p \rangle$. Finally, the binary fixed point *eq* is built on the patterns $\langle 0, 0 \rangle$ and $\langle \lambda p. s \ p, \lambda p. s \ p \rangle$.

In fact, matchers correspond to synchronous synthetic connectives, leaving out the least fixed points. In most fixed point definitions, the structure of matchers is used literally, but even when it is not strictly followed, it can be recovered by re-arranging the outermost layer of synchronous connectives, as \wedge , \vee and \exists permute with each other. Hence, any fixed point body can be assumed of the form $(\lambda p \lambda \mathbf{x}. M_{\mathcal{C}}(\phi p)\mathbf{x})$ for some patterns \mathcal{C} and predicate operator expressions ϕ .

Definition 4 (Progressing unfolding). Let \mathcal{C} be a vector $\langle \mathcal{C}_1, \dots, \mathcal{C}_n \rangle$ of patterns of the same output arity. A least fixed point instance $\mu(\lambda p \lambda \mathbf{x}. M_{\mathcal{C}}(\phi p) \mathbf{x}) \mathbf{t}$ has a progressing unfolding if $\exists \mathbf{x}. \mathbf{t} = \mathcal{C}_j \mathbf{x}$ holds for at most one $j \in \{0, \dots, n\}$.

Example 5. The formulas $\text{nat } 0$ and $\text{nat } (s \ t)$ have progressing unfoldings, for any term t , e.g., $s^n 0$, x , nil . For any h , the formulas $\text{half } 0 \ h$, $\text{half } (s \ 0) \ h$ and $\text{half } (s^2 t) \ h$ for any t have progressing unfoldings. This is not true of $\text{half } (s \ x) \ h$, because the term $s \ x$ satisfies two patterns in the definition of half . For eq , the progressing unfoldings are on instances of $\text{eq } 0 \ 0$, $\text{eq } (s \ x) \ y$ and $\text{eq } x \ (s \ y)$.

This definition is critically tied to focusing: we only inspect one synchronous synthetic connective, namely a synchronous fixed point and the outermost synchronous layer of its body. After an unfolding on the left hand-side, all absurd branches of that structure are discarded during the current asynchronous phase, and at most one remains. Symmetrically, after an unfolding on the right hand-side, at most one branch remains by the end of the synchronous phase.

Note that the definition of progressing unfolding described above does not attempt to embody a notion of termination. There is no restriction placed on the structure under the pattern, hence no guarantee that the result of the unfolding is simpler than the initial fixed point. It is in fact undecidable to identify non-termination, and not even desired, since we also want to partially explore infinite computations, as we shall see in Example 6.

4.2 Discovering (co)invariants

The construction of (co)invariants in theorem proving is an extremely difficult problem, one that has been addressed by a large number of researchers. Within the `prove` tactic, we take the following approach: we try only one invariant per possible induction site and that invariant is obtained directly from the context:

$$\frac{\Sigma; \Gamma, St \vdash G \quad \mathbf{x} ; BS\mathbf{x} \vdash S\mathbf{x}}{\Sigma; \Gamma, \mu Bt \vdash G} \quad \text{with } S := \lambda \mathbf{x}. \forall \Sigma. \mathbf{x} = \mathbf{t} \supset (\bigwedge \Gamma) \supset G.$$

With this invariant, the first premise is trivially provable, as it is essentially an instance of the identity. The second premise is where proof-search continues. This approach to induction is similar to that used in Coq, where the induction tactic always uses the current goal as the invariant. When that is not sufficient, one has to generalize the goal manually — for example by introducing a lemma.

We proceed dually for coinduction:

$$\frac{\Sigma; \Gamma \vdash St \quad \mathbf{x} ; S\mathbf{x} \vdash BS\mathbf{x}}{\Sigma; \Gamma \vdash \nu Bt} \quad \text{with } S := \lambda \mathbf{x}. \exists \Sigma. \mathbf{x} = \mathbf{t} \wedge (\bigwedge \Gamma).$$

Such trivial (co)inductions suffice for many examples. For example, when proving $\forall p. \text{sim } p \ p$, the context does provide a coinvariant: $\lambda p_1 \lambda p_2. \exists p. p_1 = p \wedge p = p_2$: that is, $\lambda p_1 \lambda p_2. p_1 = p_2$.

Example 6. Consider the following theorem of μLJ : $\forall x. eq (s x) (s (s x)) \supset \perp$. In the asynchronous phase, \forall and \supset are introduced, after which the fixed point has to be treated. It is either frozen (which obviously cannot yield a proof here) or inducted on, which can be done in two ways. One possibility is to attempt to prove that the context $(\lambda m \lambda n. \forall x. m = s x \supset n = s (s x) \supset \perp)$ is an invariant, which is not true. The other possibility is to perform the progressing unfolding of the fixed point, in which case we obtain the subgoal $eq x (s x) \vdash \perp$. At this point one can quickly obtain a proof, as the context is an invariant: $\lambda m \lambda n. n = s m \supset \perp$. Notice that performing another progressing unfolding of eq would loop, producing the same subgoal.

4.3 Organization of the prove tactic

In order to build a practical theorem proving tactic within our focused proof system, several compromises must be made and these compromises will result, ultimately, in the lost of completeness. In particular, we need to clarify the design of proof-search in the asynchronous phase and we need to ensure termination.

Except for freezing, all asynchronous rules are invertible – in the case of induction, this is obtained by instantiating it into a left unfolding. However, from a bottom-up proof-search point of view, this does not mean that these rules can be applied eagerly without backtracking. Namely, a least fixed point instance on the left can be treated in a number of different ways: it may be frozen, inducted on with an arbitrary invariant, or unfolded, perhaps in a progressing way. Our approach is to postpone these choices as much as possible, first applying all non-backtracking asynchronous rules. Moreover, we only (co)induct using (co)invariants generated as previously described, and we perform progressing unfoldings eagerly, without backtracking, reflecting their deterministic nature. Therefore the asynchronous phase proceeds as follows: (1) apply the non-backtracking asynchronous rules, (2) try for each remaining asynchronous fixed point to either freeze, (co)induct or unfold¹, backtracking on those possibilities, and coming back to Step (1) after each attempt.

The usual problem of such procedures is that they may encounter infinite branches during search. In μLJ such branches are caused by contractions, fixed point unfoldings, and (co)induction. A common way to address this issue is to bound the depth of search. This technique can be too rough, but we tame its downsides by applying it on the higher-level architecture developed in this paper. Once again the issue lies in the distinction between computation and deduction. We make use of a *deductive* bound, attached to individual sequents, which limits the number of non-progressing fixed point unfoldings, (co)inductions, and contractions in one branch. Moreover, we introduce a *computational* bound to limit the number of progressing unfoldings performed on a given fixed point. Computational bounds must be attached to individual formulas: since progressing

¹ It might be surprising that we attain the best results by attempting (co)induction before unfolding; this is because these non-progressing unfoldings are rarely useful.

unfoldings are performed eagerly, we must prevent one chain of such unfoldings from starving another. The deductive bound controls the number of critical choices made in a proof, and therefore the complexity of proof-search, increasing the bound even slightly could lead to significantly longer attempts. However, since computations are factored out of the deductive bound, a low bound typically suffices; as a default we perform iterative deepening up to a depth of 3. In contrast, the computational bound can be set much higher without affecting the cost of proof-search. This design has proved critical to the success of our tactic.

5 Comparison and experimental results

In order to show the strengths of our approach, we provide several examples of its successes in Figure 5 and use them to compare Tac with two established inductive theorem provers. The first group of examples come from the IWC suite (<http://www.cs.nott.ac.uk/~lad/research/challenges>) and the second one from Twelf’s examples. The last group consists of interesting original examples leveraging Tac’s specificities: *sim* illustrates that Tac deals with coinductive definitions and coinduction just as naturally as with inductive definitions; the other examples show interesting developments² that exploit Tac’s support for generic quantification [3] and the role that the automatic tactic `prove` can play within interactive proof development. We do not provide timings since our implementation was not optimized for speed, but stress that all automated examples pass in less than a few seconds. The implementation, including all of the examples mentioned in this paper, is available at <http://slimmer.gforge.inria.fr/tac/>.

5.1 Comparison with rewriting based approaches

Rewriting based approaches to inductive theorem proving are common: for example, ACL2 and the many provers that make use of rippling. These specialized foundations, together with refined heuristics, make for powerful tools, but also have some drawbacks. Notably, they do not provide as solid proof witnesses as sequent calculus, and in general cannot be related to general-purpose proof assistants such as Coq or Isabelle. The IWC challenges highlight the main differences between our approach and rewriting-based techniques.

Several challenges were infeasible in Tac because they relied too heavily on equational reasoning. When stated in a relational way in our tool, the complexity of such statements increases a lot: for example, $(x+y)+z = t$ becomes $\exists i. x+y = i \wedge i+z = t$. This weakness is not so important in application areas such as operational semantics, where commutativity and associativity are rarely relevant and equational reasoning is little used.

On the other hand, the challenges that Tac passed show that our relatively straightforward but general approach replicates reasoning schemes that have to

² In our current development of the POPLMark problem 2A, some details are missing but we see no obstacles in completing the problem soon.

Name	Description	Auto	Lemma
IWC 02	$append(l, l')$ of even length iff $append(l', l)$ too	Yes	No
IWC 03	$x \in l$ implies $x \in append(l, l')$	Yes	No
IWC 04	$l = rotate(length(l), l)$	No	Yes
IWC 06	eq. of mutual and straight definitions of even	Yes	No
IWC 07	natural numbers are even or odd	Yes	No
IWC 12	verifying abstractions in model checking	No	Yes
IWC 16	whisky problem	Yes	Yes
plus	commutativity and associativity of <i>plus</i>	Yes	No
arith	totality of many Horn programs, <i>e.g.</i> , <i>half</i> , <i>ack</i>	Yes	No
prop-calc	Hilbert’s abstraction theorem	Yes	No
reverse	involutivity of list reversal	Yes	No
binarytree	antisymmetry of the subtree ordering on binary trees	Yes	No
sim	reflexivity and transitivity of <i>sim</i>	Yes	No
PCF	subject reduction and determinacy of typing for PCF	No	Yes
POPL-1A	transitivity of subtyping for F^{\leq}	No	Yes

Fig. 5. Examples of Tac proofs. The “Lemma” column indicates whether a lemma needed to be manually introduced, and “Auto” indicates that **prove** automatically derived all lemmas and theorems.

be implemented as special techniques in rewriting and termination-based approaches, such as case analysis, generalization, simultaneous and mutual induction schemes. Our single induction principle and limited invariant generation already embeds an interesting amount of generalization, and the nesting and interleaving of inductions gives rise to complex induction schemes (corresponding, for example, to multiset and lexicographic orderings). This is visible in some of our custom examples such as the totality of *ack* or the involutivity of list reversal.

In some cases, it is unreasonable to expect an automatic proof: some human will need to introduce explicitly generalizations or lemmas. The same goes for all provers and Tac is no exception. In our test suite, once lemmas were stated, Tac was able to prove them automatically and deduce the final theorem. In IWC challenges 4 and 12, however, some non-trivial human guidance was required in this process.

5.2 Comparison with Twelf

Twelf [13] allows writing specifications in LF, a dependently typed intuitionistic framework, and can perform proof-search in LF as well as meta-reasoning about LF specifications. Meta-reasoning is done in two ways.

First, Twelf is equipped with a number of specialized procedures for establishing whether some LF relation is total, functional, etc. That feature is well developed and widely used. We can replicate many of the established meta-theorems, but those dedicated procedures outperform our generic tactic, which

is not able to re-use properties of nested fixed points. It should be noted, however, that in order to check a totality assertion, a termination order should be explicitly give, while our system infers it.

Secondly, Twelf has a more generic meta-theorem prover [13] which searches for proofs in the \mathcal{M}_2 meta-logic, whose objects are LF terms. This logic only deals with Π_2 statements and Twelf implements a simply structured proof-search strategy for them. The main phases of this strategy can be formulated in terms of focusing, but their general organization differs. Notably, this strategy only attempts an outermost induction, whose validity is based on a termination ordering provided by the user. In contrast, the (co)invariant generation of Tac can discover induction schemes without assistance from the user and can notably use nested inductions to discover proofs that are inaccessible to Twelf. A striking example is the involutivity of list reversal, which Tac proves without any additional lemmas thanks to nested inductions. On the other hand, Twelf can sometimes prove a theorem, *e.g.*, the totality of *half*, using a single induction when Tac would require nested inductions, since Twelf’s meta-logic allows the use of an induction hypothesis on an arbitrary predecessor, while our scheme corresponds to restricting to the immediate predecessor. Finally, there is no notion of progress in Twelf’s meta-theorem prover, which results in a critical need to tweak bounds.

The major strength of Twelf is not so much the architecture of its proof-search strategy, but the expressivity of the LF objects manipulated in the \mathcal{M}_2 logic. Twelf handles higher-order abstract syntax (HOAS) specifications easily, enabling its simple meta-theorem prover to prove important results such as type preservation and progress for programming languages. Tac supports higher-order terms and features minimal generic quantification [3] to expressively reason about such objects. Focused proof search is not affected by the introduction of these rich notions, and **prove** indeed handles them without any modification. But HOAS notably involves dealing with hypothetical contexts, for which there is no built-in support in Tac. When working with such contexts in Tac one must therefore implement them by hand, generally using lists, which tends to create artificial details. As a result, while Tac seems to be in general more powerful than Twelf on examples not involving HOAS, it is unable to carry out automatically developments significantly dealing with hypothetical contexts. However, since Tac is an interactive proof assistant, the user can guide the proving of such theorems, still benefiting from **prove** to fill in many simple proof obligations.

6 Conclusion

We have shown how the important, proof-theoretic notion of a focused proof system can be applied to the construction of an inductive theorem prover. The Tac prover is capable of proving many non-trivial theorems, which is particularly impressive given the genericity and simplicity of its design.

There are a number of ways to enhance the current system. A general challenge with proof-search and our treatment of equality lies in the handling of

logical variables in left hand-side equalities, which obviously hinders automated proof search in several examples. We are currently exploring ways to address this unusual aspect of unification. We also plan to explore more the use of flexibilities in polarity assignment left in the design of focused systems for μ LJ. In our experience, such choices can have an important impact on proof-search. It is also crucial that we develop efficient techniques for re-using previously proved lemmas — a common problem in theorem proving.

Acknowledgments. The authors wish to thank Alexandre Viel for his help in developing Tac and the reviewers of an earlier version of this paper for their comments.
